Abstract

Sandstones are sedimentary rocks formed from cemented sand-sized clasts. The cement that binds the clasts can vary from clay minerals to ca, silica or iron oxides. Sandstone can be further divided according to: Clast size – fine (0.06-0.2mm), medium (0.2-0.6mm), coarse (0.6-2mm); Sorting - poorly sorted, moderately well sorted and well sorted. Sandstones could also be discussed in terms of little or significant amount of silt and / or clay as arenaceous or argillaceous (wacke). Nine (9) samples were collected from the Ilaro sandstone and subjected to granulometric, petrographic and geochemical analysis precisely ICP-MS (Inductively coupled plasma mass spectrometry) for the major elements and their oxides. Granulometric analysis reveals that the texture of the sediments ranged from medium to coarse through to very coarse, they are symmetrically skewed and dominantly mesokurtic. Bivariate plot however depicts the Ilaro sandstone to be fluvatile in their depo-setting. All the samples also showed strong inclination towards sub-greywacke in terms of their geochemical classification.

Keyword: granulometric; mesokurtic; fluvatile; sub-greywacke; sandstone.

1. Introduction

The Ilaro sandstone conformably overlies the Oshosun Formation and it consists of massive, yellowish, poorly consolidated, fine to coarse, cross-bedded sandstones with thin clays and shales.

* Corresponding author.

It is part of the Dahomey basin and of Eocene age. Sandstone, sometimes known as arenite, is a clastic sedimentary rock comprised of sand-sized minerals or rock grains. Most sandstone is composed of quartz and/or feldspar because these are the most common minerals in the earth's crust. Like sand, sandstone can be any color but the most common colors are tan, brown, yellow, red, grey, pink, white and black. Rock formations that are primarily composed of sandstone usually allow percolation of water and other fluids and are porous enough to store large quantities, making them valuable aquifers and petroleum reservoirs. Sandstones are clastic in origin (as opposed to either organic, like chalk and coal or chemical like gypsum and jasper). They are formed from cemented grains that may either be fragments of a pre-existing rock or be mono-mineralic crystals. The cement binding these grains together is typically calcite, clays and silica. The formation of sandstone involves two principal stages: First, a layer or layers of sand accumulate as a result of sedimentation, either from water (stream, lake and sea) or from air (as in a desert). The environment where the sandstone is deposited is crucial in determining the characteristics of the resulting sandstone, which, in finer detail, include its grain size, sorting, and composition and, in more general detail, include the rock geometry and sedimentary structures. Principal environments of deposition may be split between terrestrial and marine as illustrated by the following broad groupings:

1.1 Terrestrial Environment

- Rivers (levees, point bars, channel sands), Alluvial fans, Glacial outwash, Lakes, Deserts (sand dunes and ergs)

1.2 Marine Environments

- Deltas, Beach and shoreface sand, Tidal flats, Offshore bars and sand waves, Storm deposits (tempestites). Turbidites (submarine channels and fans). Generally, the study area is on a relief of 200m above sea level and lies between latitude $6^{\circ}50'$ and $6^{\circ}57'N$ and longitude $2^{\circ}58'$ and $3^{\circ}05'E$. The formation falls around Kajola Abalabi in Ilaro south western part of Nigeria. Fig.2 The study area is accessible through Papalanto-Ifo road towards Ilaro town. It is also accessible by a major road, minor roads and several footpaths. The formation is exposed as a massive road cut.

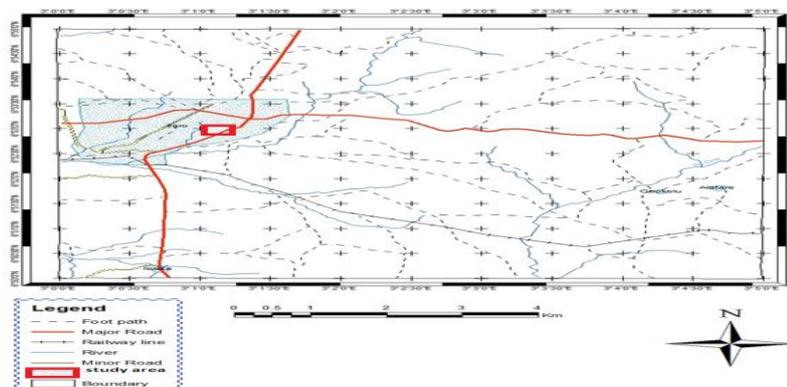

Figure 1: Drainage and accessibility map of the study area

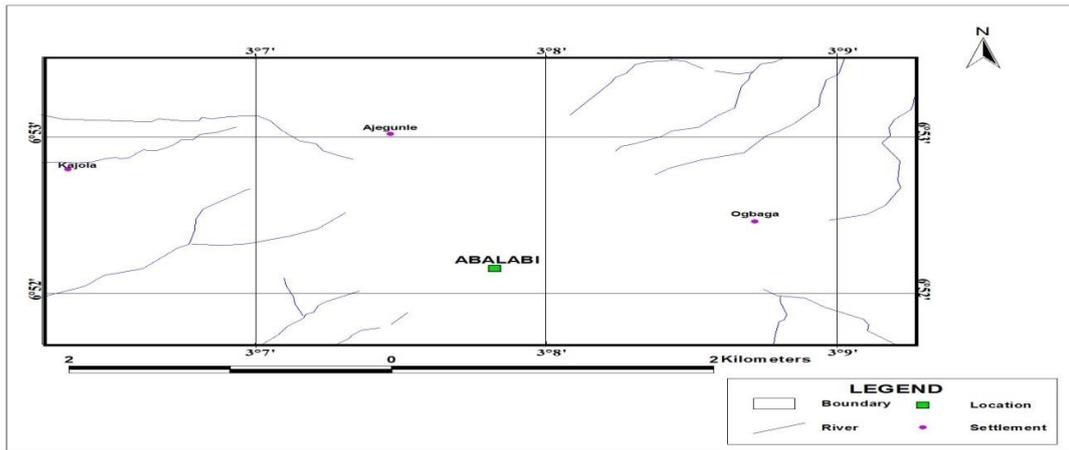

Figure 2: Location of the study Area.

This research paper aims at unraveling the depositional setting using granulometric analysis as well as further classifying the Ilaro sandstone based on result of geochemical analysis.

2. Materials and Method

The study area was traversed by foot and detailed geological mapping of the exposed sandstone was carried out. The co-ordinate and elevation of the outcrop above sea level were first recorded with the aid of a G.P.S (Global positioning System). Visually observable features were carefully mapped and recorded accordingly. These include color, texture, lithological unit, bedding pattern, presence of ichno fossils, visible minerals as well as intensity of weathering. strikes and dips readings were taken along the bedding planes of each litho-unit with the aid of compass clinometers to determine the trending pattern of the road-cut exposure, The entire road-cut exposure was logged and the thickness of each litho-unit was recorded. Nine samples were later collected from different litho-unit into sample bags and labeled with the use of a masking tape accordingly as L1 to L9 for ease of identification. The samples were then subjected to granulometric, petrographic and geochemical analysis. For granulometric analysis, initial weight of 50g of slightly pulverized sample was used, which was run through sieve openings of graded diameter (μm). Thin sections were also made for samples L1 to L9 and then viewed under petrologic microscope in both plane polarized light and under crossed nicol for mineral identification and modal composition of the inherent minerals in the Ilaro Sandstone.. Photomicrographs of all the slides were then shot in both plane polarized light and under crossed nicol. Geochemical analysis was resolved using ICP-MS (Inductively Coupled Plasma Mass Spectrometry) about 25g of each sample were pulverized into powdery form and major, trace and rare earth elements were analysed for, although the major elemental oxides were employed for geochemical calculations. Criteria for the classification of sandstones were further employed in classifying the Ilaro sandstone [1].

3. Literature Review

Authors in [2] Worked on the geochemistry and mineralogy of the Imobi sandstones. The study was aimed at inferring the provenance and possible depositional environment for these sandstones. Eight rock samples

from the study area were subjected to geochemical analysis using X-ray fluorescence in order to determine the chemical composition. Parts of the samples were also used for mineralogical analysis to determine mineralogical compositions and to estimate the modal percentages of minerals in the Imobi sandstone samples. Geochemical analysis revealed sixteen elements and their oxides which includes SiO₂, Al₂O₃, Fe₂O₃, CaO, V₂O₅, ZrO₂, SO₃, K₂O, Br, P₂O₅, CuO, TiO₂, MnO, Rb₂O, As₂O₃, Cr₂O₃. However mineralogical study shows the presence of three minerals along with accessory minerals, they include quartz, iron oxide, microcline and some accessory minerals. The presence of element and elemental oxides such as Br, V₂O₅, ZrO₂, Cu₂O, Rb₂O, As₂O₃ and MnO (especially Br which occurred in a recognizable quantity of about 12%-27%) suggests the depositional environment of the Imobi sandstone to be a shallow marine or near marine environment. However the abundance of Fe₂O₃ infers the derivation of the sediments from a metamorphic source.

4. Geology and Stratigraphy of the Basin

The Dahomey Basin, which is also referred to as, Benin Basin, or West Nigerian Basin, extends from south-eastern Ghana in the West, through Southern Togo and southern Benin Republic (formerly Dahomey) to Southwest Nigeria. The western flank of the Niger delta to be precise Fig 4. The axis of the basin and the thickest sediments occur slightly west of the border between Nigeria and Benin Republic. The basin is bounded on the west by faults and other tectonic structures. Its eastern limit is marked by the Benin Hinge line, a major fault structure marking the western limit of the Niger delta basin. To the west of the Benin Hinge line is the Okitipupa Ridge [4]. The tertiary sediments of the Dahomey basin thin out and are partially cut off from the sediments of the Niger delta basin against this ridge of basement rocks. The basin's offshore limit is similarly marked by the Hinge line, a major bounded in the north by the Precambrian fault structure marking the western limit of Niger Delta [5]. It is also basement rock and the Bight of Benin in the south. The stratigraphy of Dahomey basin to which the Ilaro sandstone belongs had been resolved by several workers including; [4]

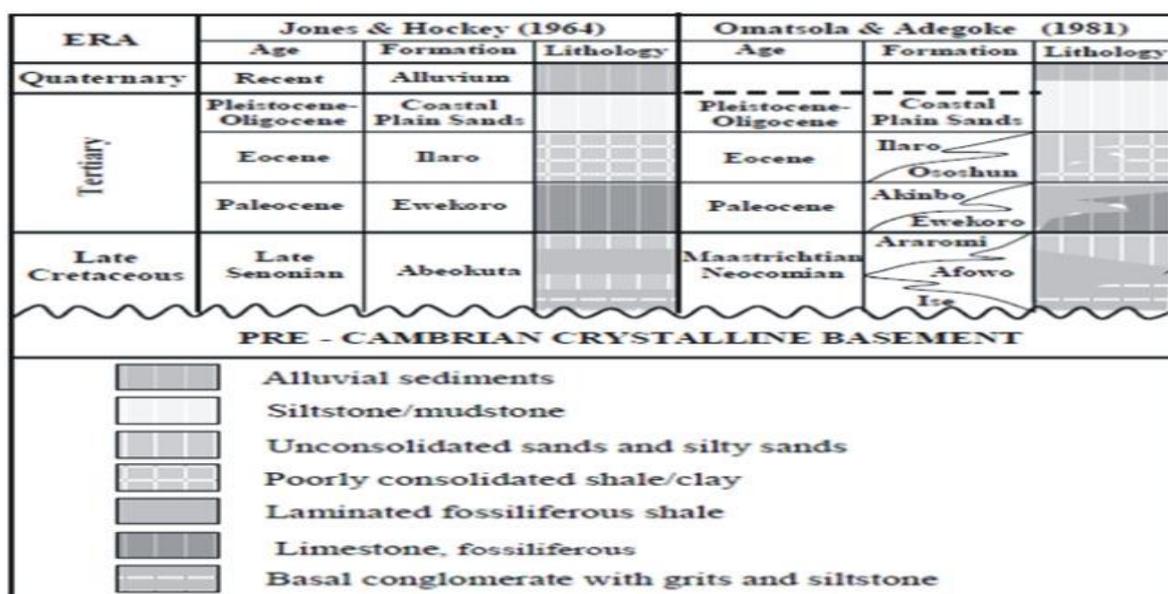

Figure 3: The Stratigraphy of Eastern Dahomey [6]

The general sequence for the rock unit from the top are the Coastal plain sands, Iaro formation, Oshosun formation, Akinbo formation, Ewekoro formation, and Abeokuta formation lying on the South western Basement Complex of Nigeria. The Dahomey basin is an extensive sedimentary basin in the Gulf of Guinea. It extends from south-eastern Ghana through Togo and Benin Republic on the west side to the Okitipupa ridge/Benin Hinge line on the west of Niger Delta

The following are the parameter for the classification of sandstones based on chemical approach. They are used according to [9]

- 1) Quartz arenite: $\log (\text{SiO}_2/\text{Al}_2\text{O}_3) \geq 1.5$
- 2) Greywacke: $\log (\text{SiO}_2/\text{Al}_2\text{O}_3) < 1$ and $\log (\text{K}_2\text{O}/\text{Na}_2\text{O}) < 0$
- 3) Arkose (includes subarkose): $\log (\text{SiO}_2/\text{Al}_2\text{O}_3) < 1.5$ and $\log (\text{K}_2\text{O}/\text{Na}_2\text{O}) \geq 0$ and $\log ((\text{Fe}_2\text{O}_3+\text{MgO})/(\text{K}_2\text{O}+\text{Na}_2\text{O})) < 0$
- 4) Lithic arenite (subgraywacke, includes protoquartzite): $\log (\text{SiO}_2/\text{Al}_2\text{O}_3) < 1.5$ and either $\log (\text{K}_2\text{O}/\text{Na}_2\text{O}) < 0$ or $\log ((\text{Fe}_2\text{O}_3+\text{MgO})/(\text{K}_2\text{O}+\text{Na}_2\text{O})) \geq 0$. If $\log (\text{K}_2\text{O}/\text{Na}_2\text{O}) < 0$, lithic arenite can be confused with graywacke. The coastal plain sediments fall within the requirements of the third condition and thus classified as an arkose (includes subarkose).

6. Conclusion

The presence of brownish red and purple coloration in the quartz shows the presence of hematite (Fe₂O₃) and they are typical of non- marine environment. Formations located in warm, humid climates often develop such coloration of quartz, showing that there is insufficient organic matter present to reduce the ferric iron to the relatively soluble ferrous state [10].

The presence of more than 15% of matrix in the rock samples shows is a greywacke and a greywacke is a high grade diagenetic or low grade metamorphic product.

The presence of larger clasts of quartz in the sandstone shows the sandstone is most likely deposited in high energy environments and is transported with lower energy making it have lesser impacts of weathering. They are characteristics of submarine fan, slope, and abyssal deposits. Detrital modes of sandstone also provide information about the tectonic settings of basins of deposition [11].

The relationship between sandstone petrography and tectonic setting has been studied by many authors

Acknowledgement

The author acknowledges the unflinching effort and support of Miss Lawal T.O and Mr. Olajolumo O. who assisted during the field work. Furthermore, Mr. Ibikunle O. and Mr. Oyekan O.O, Technologist of the department of Civil Engineering and Earth Sciences of Ladoko Akintola University of Technology, Ogbomoso, Oyo State Nigeria are greatly appreciated for their availability and immense assistance in the course of running the sieve analysis.
